Abstract. Statistical emulation of process-based crop models provides the opportunity to combine advantageous features of statistical and process-based crop models. The Global Gridded Model Intercomparison Project (GGCMI) Phase II consists of a set of simulations run on a suit of process based models with an explicit goal of producing a structured training dataset for crop model emulator development across four dimensions: atmospheric carbon dioxide (CO₂) concentrations, temperature, water supply, and nitrogen inputs (CTWN). These training datasets are available for two contrasting assumptions on growing season adaption: fixed growing seasons (through adaptation in cultivar choice) and growing seasons shortening in warmer climates (assuming no adaptation in cultivar choice). In this study we present the construction of a set of crop model emulators of mean-climatological yield for nine process-based crop models and five crops. After presenting the rationale and technical

implementation of the emulator construction, we evaluate the emulator performance and discuss the general applicability of these emulators as well as individual cases, where the emulators show unexpected behavior. The climatological mean yield response can be readily represented with a simple polynomial in almost all locations where crops are currently grown, permitting a tool that captures model responses in a lightweight, computationally tractable form. The crop model emulators
5 presented here should therefore facilitate both model comparison and integrated assessment of climate impacts.

1 Introduction

Improving our understanding of the impacts of future climate change on crop yields is critical for global food security in the twenty-first century. Projections of future yields under climate change are generally made with one of two approaches: either process-based models, which simulate the process of photosynthesis and the biology and phenology of individual crops, or
10 statistical models, which use historical weather and yield data to capture relationships between observed crop yields and major drivers. Process-based crop models provide some advantages, including capturing the direct effects of CO₂ fertilization and allowing projections in areas where crops are not currently grown. However, they are computationally expensive, and can be difficult or impossible to directly integrate into integrated climate change impacts assessments. Statistical crop models can only capture crop responses under the range of current conditions, but have several advantages: they implicitly include management
15 and behavioral practices that are difficult to model explicitly, and they are typically simple analytical expressions that are easily implemented by downstream impact modelers. Both types of models are routinely used, and comparative studies have concluded that when done carefully, both approaches can provide similar yield estimates (e.g. Lobell and Burke, 2010; Moore et al., 2017; Roberts et al., 2017; Zhao et al., 2017; Liu et al., 2016a).

Statistical emulation allows combining some of the advantageous features of both statistical and process-based models.
20 The approach involves constructing a “surrogate model” of numerical simulations by using their output as training data for a statistical representation (e.g. O’Hagan, 2006; Conti et al., 2009). Emulation is particularly useful in cases where simulations are complex and output data volumes are large, and has been used in a variety of fields, including hydrology (e.g. Razavi et al., 2012), engineering (e.g. Storlie et al., 2009), environmental sciences (e.g. Ratto et al., 2012), and climate (e.g. Castruccio et al., 2014; Holden et al., 2014). For agricultural impacts studies, emulation of process-based models allows capturing key
25 relationships between input variables in a lightweight, flexible form that is compatible with economic studies. The resultant statistical model can produce yield projections under arbitrary emissions scenarios and is an important diagnostic tool for model comparison and model evaluation.

Interest is rising in applying statistical emulation to crop models, and multiple studies have developed crop model emulators in the past decade. Early studies proposing or describing potential crop yield emulators include Howden and Crimp (2005);
30 Räisänen and Ruokolainen (2006); Lobell and Burke (2010), and Ferrise et al. (2011). Studies developing single-model emulators include Holzkämper et al. (2012) for the CropSyst model, Ruane et al. (2013) for the CERES wheat model, and Oyebamiji et al. (2015) for the LPJmL model. More recently, emulators have begun to be used in the context of multi-model intercomparison, with multiple authors (Blanc and Sultan, 2015; Blanc, 2017; Ostberg et al., 2018; Mistry et al., 2017) using them to

analyze the five crop models of the Inter-Sectoral Impact Model Intercomparison Project (ISIMIP). ISIMIP offers a relatively large training set – control, historical, and several Representative Concentration Pathway (RCP) scenarios using output from up to five climate models (Warszawski et al., 2014; Frieler et al., 2017) – and choices of emulation strategy differ. Blanc and Sultan (2015) and Blanc (2017) use historical and RPC8.5 scenarios, combine multiple climate model projections for RCP8.5, 5 and regress across soil regions. Ostberg et al. (2018) use global mean temperature change (and CO₂) as regressors, and then pattern-scales to emulate local yields. Mistry et al. (2017) compare emulated and observed historical yields, using local weather data and a historical crop simulation. The constraints of the ISIMIP experiment mean that all these efforts do share important common features. All emulate annual crop yields along an entire scenario or scenarios, and all future climate scenarios are non-stationary, with important covariates (temperature and precipitation for example) evolving simultaneously.

10 An alternative approach to emulation involves construction of a “parameter sweep” training set, a collection of multiple stationary scenarios that systematically cover a range of input parameter values. A parameter sweep offers several important advantages for emulation over an experiment in which climate evolves over time. First, it allows separating the effects of different variables that affect yields but that are highly correlated in realistic future scenarios like those used in ISIMIP (e.g. CO₂ and temperature). Second, it allows making a distinction between year-over-year yield variations and climatological 15 changes, which may involve different responses to the particular climate regressors used (e.g. Ruane et al., 2016). For example, if year-over-year yield variations are driven predominantly by variations in the distribution of temperatures throughout the growing period, and long-term climate changes are driven predominantly by additive mean shifts, then regressing on the mean growing period temperature will produce different yield responses at annual vs. climatological timescales.

Systematic parameter sweeps have begun to be used in crop model evaluation and emulation, with early efforts in 2014 and 20 2015 (Ruane et al., 2014; Makowski et al., 2015; Pirttioja et al., 2015), and several recent studies in 2018 and 2019 (Fronzek et al., 2018; Ruiz-Ramos et al., 2018; Snyder et al., 2019). These three studies sample multiple perturbations to temperature and precipitation, and two of the three add CO₂ as well, for a total of 132, 99 and 220 different combinations, respectively. All take advantage of the structured training set to construct emulators (“response surfaces”) of climatological mean yields, omitting year-over-year variations. All the 2018–2019 papers have some limitations, however, for assessing global agricultural impacts, 25 including that none evaluate responses in every grid cell globally. Two involve many crop models but only one crop (wheat) (Fronzek et al., 2018; Ruiz-Ramos et al., 2018) and cover only 1–4 individual sites. Snyder et al. (2019) analyzes five crops over ~1000 sites with individual site-specific crop models, and extrapolates in space to estimate mean latitudinal responses.

In this paper we describe a set of globally-gridded crop model emulators developed from the new parameter-sweep dataset of the Global Gridded Crop Model Intercomparison (GGCMI) Phase II effort. GGCMI Phase II, a part of the Agricultural Model 30 Intercomparison and Improvement Project (AgMIP) (Rosenzweig et al., 2013, 2014), provides the first near-global-coverage systematic parameter sweep of multi-model crop simulations consisting of up to 756 combinations in CO₂, temperature, water supply, applied nitrogen, and two counterfactual assumptions on growing season adaptation (“A0”: none and “A1”: regaining growing season length) (CTWN-A, Franke et al., 2019; Minoli et al.) . The experiment is designed to allow diagnosing the impacts on crop yields of both individual factors and their joint effects, and to allow construction of crop model emulators. In

the following, we describe the training dataset (Section 2), the statistical model used for emulation (Section 3), measures of emulator fidelity (Section 4), and examples of preliminary results (Section 5).

2 Training dataset

2.1 The GGCMI Phase II dataset

Table 1. Crop models included in GGCMI Phase II emulators and the number of CTWN-A (Carbon, Temperature, Water, Nitrogen, Adaptation) simulations performed for each model. The maximum number is 756 for A0 (no adaptation) experiments, and 648 for A1 (maintaining growing length) experiments, since T0 is not simulated under A1. “N-Dim.” indicates whether the models are able to represent varying nitrogen levels. Each model provides the same set of CTWN simulations across all its modeled crops, but some models omit individual crops. Table adapted from Franke et al. (2019). For clarity, three simulation models included in Phase II are not shown here, those that provided a training set too small to be used in emulation.

Model (Key Citations)	Maize	Soybean	Rice	Winter wheat	Spring wheat	N dim.	Sims per crop (A0 / A1)

5 The GGCMI Phase II simulations are described in detail in Franke et al. (2019), but we summarize briefly here. The experiment involves nine different globally gridded crop models, each simulating multiple crops (maize, rice, soybean, and spring and winter wheat) across a systematic parameter sweep of as many as 756 combinations, each driven by a historical climate

Table 2. GGCMI Phase II input levels for the parameter sweep. Values for temperature and water supply are perturbations from the historical climatology. For water supply, perturbations are fractional changes to historical precipitation, except in the irrigated (W_∞) simulations, which are all performed with the maximum beneficial levels of water. Bold font indicates the ‘baseline’ historical level. The full protocol samples across all parameter combinations for a total of 756 cases. Table repeated from Franke et al. (2019).

Input variable	Tested range	Unit
[CO ₂] (C)	360 , 510, 660, 810	ppm
Temperature (T)	-1, 0 , 1, 2, 3, 4, 6	°C
Precipitation (W)	-50, -30, -20, -10, 0 , 10, 20, 30, (and W_∞)	%
Applied nitrogen (N)	10, 60, 200	kg ha ⁻¹
Adaptation (A)	A0: none , A1: new cultivar to maintain original growing season length	-

timeseries with systematic perturbations to CO₂, temperature, water supply, and nitrogen application (CTWN). The simulation protocol involves 4 levels of atmospheric CO₂, 7 of temperature, 9 of water supply, and 3 of applied nitrogen, and simulations are repeated for two adaptation scenarios: “A0” simulations assume no adaptation in cultivar choice, so that growing seasons shorten in warmer climates, and “A1” simulations assume that adaptation in cultivar choice maintains fixed growing seasons.

- 5 The complete protocol for each modeling group involves up to 43,524 years of global simulated output for each crop. Because the computational demand is high, modeling groups were allowed to submit at various specified levels of participation, with the lowest recommended level of participation consisting of 20% of the maximum possible simulations. The mean participation level is 65%, but three models (APSIM-UGOE, EPIC-IIASA, and ORCHIDEE-crop) contributed data below the recommended threshold (< 5% of the full protocol) and are excluded here since they could not be robustly emulated. Table 1 shows the participating models and the number of simulation scenarios that each provides, and Supplemental Figure S1 shows model sampling density. Table 2 shows the specified input values; we sample across all parameter combinations.

10 Each individual crop model simulation is run for 31 years over historic weather for the period of 1981-2010, with added uniform perturbations to any of the CTWN variables. Historical weather is taken for most models from the AgMERRA (Ruane et al., 2015) historical daily climate data product, but the PROMET model uses the ERA-Interim reanalysis (Dee et al., 2011) and the JULES model uses a bias-corrected version of ERA-Interim, WFDEI (WATCH-Forcing-Data-ERA-Interim) (Weedon et al., 2014) as these groups have specific sub-daily input data requirements. Temperature perturbations are applied as additive mean shifts, water supply as fractional multipliers to precipitation (except in the irrigated W_∞ case), and CO₂ and nitrogen application levels are specified as fixed values. Models provide near-global output at 0.5 degree latitude and longitude resolution for each simulation year, including areas not currently cultivated. In analyses where we distinguish yields over currently 15 cultivated land, we use the masks of Portmann et al. (2010). See Supplemental Figures S2 and S3 for maps of cultivation area.

2.2 Climatological vs. year-to-year response

We emulate the climatological mean response, because that is the response of interest in assessments of climate change impacts. The year-over-year response can be significantly different from the forced climatological one, so we do not use information from year-to-year variability but instead emulate the aggregated mean yield in each 30-year simulation. Emulation
5 then becomes relatively straightforward, since changes in time-averaged yields are also considerably smoother than those in year-to-year yield response.

In the GGCMI Phase II simulation output dataset, year-over-year responses to weather are often quantitatively distinct from responses to climatological shifts, with the discrepancy especially strong in wheat and rice. The difference in behavior is illustrated in Figure 1, which shows irrigated and rainfed maize and wheat in representative locations; open circles and black
10 lines show the climatological mean response, and solid circles and colored lines the responses for the 30 individual years in individual scenarios. When discrepancies are large, year-over-year responses are generally stronger than climatological ones, but exact responses differ by crop and region and even by model within GGCMI Phase II.

While differences in responses at different timescales can arise for many reasons, including memory in the crop model or lurking covariates, the most likely explanation here is that the regressors used, mean growing-season temperature or precipitation, do not fully describe the conditions that affect crop yields. The mean growing-season value is only a proxy for the distribution of daily climatic conditions that crops are sensitive to, and present-day variations between years can be very different from future forced changes. That is, variations in growing-season *means* from year to year at present are associated with changes in growing-season *distributions* that are unrelated to any changes in future warmer climates: a warm year at present may be quite different from a warm year in the future (e.g. Ruane et al., 2016). Changes in temperature distributions have been
20 shown to strongly affect crop yields (e.g. Hansen and Jones, 2000; Gadgil et al., 2002), though precipitation effects should be smaller since crops respond not to rainfall but to soil moisture, which integrates over weeks or even months (e.g. Potter et al., 2005; Glotter et al., 2014; Challinor et al., 2004).

A second factor of importance is that any nonlinearity in crop responses will itself lead to a distinction between climatological and year-over-year fits, even if distributional differences are irrelevant. Given the interannual variations in the climate
25 timeseries, the mean annual yield response to a perturbation is not the same as the response of the climatological mean yield. The effect of nonlinearity may be particularly relevant for precipitation, since model crop yields drop steeply and nonlinearly with increasing dryness. (Crop yields should drop under excess precipitation as well, but process-based models do not capture losses in saturated conditions well (e.g. Glotter et al., 2015; Li et al., 2019).)

In the GGCMI Phase II experiment, the imposed perturbations involve no changes in underlying distributions. The choice
30 is reasonable, since climate models do not agree on distributional changes. Most models do project small mean increases in growing-season temperature variability in cultivated areas, and can produce substantial local changes, but models disagree on spatial patterns. For example, in the high-end (Representative Concentration Pathway (RCP) 8.5 (Riahi et al., 2011)) climate projections to the year 2100 in the Coupled Model Intercomparison Project Phase 5 (CMIP-5) archive, growing season temperature variability over currently cultivated rice areas increases by 31% in HadCM3L but decreases by 12% in CESM1-0-1.

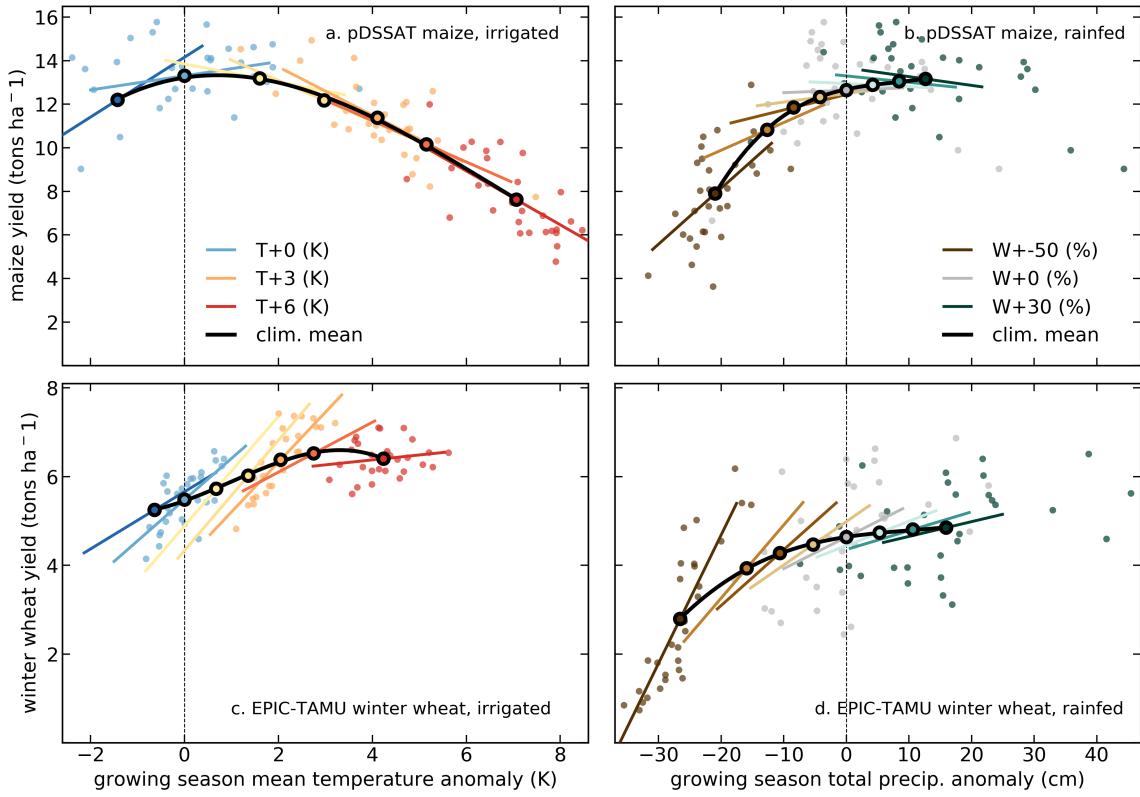

Figure 1. Example showing distinction between crop yield responses to year-to-year and climatological mean shifts in climate variables, showing representative high-yield regions for maize in pDSSAT (northern Iowa, top row) and winter wheat in EPIC-TAMU (France, bottom row). Left column (**a** & **c**) shows irrigated crops, all temperature cases with other variables held at baseline values, and right column (**b** & **d**) shows rainfed crops, all precipitation cases. Figure shows A0 output, in which growing seasons shift under future climate, so local growing-season temperature changes can differ from prescribed uniform offsets: for example, a 5 K applied uniform warming results in a growing season temperature warmer by ~7 K for maize in Iowa (top right), but by less than 5 K for wheat in France (bottom right). Open black circles mark climatological mean yields and bold black lines show a 3rd order polynomial fit through them. Colored lines show linear regressions (by orthogonal distance regression) through the 30 annual yields of each parameter case. Colored circles show annual yields for selected cases. Differences in slopes of colored and black lines mean that responses to year-over-year fluctuations differ from those to longer-term climate shifts. Differences are generally stronger for wheat (bottom) than maize (top). Note that for rain-fed crops, slope differences in this representation could also result from correlated precipitation and temperature fluctuations in the baseline timeseries, but P-T correlations do not contribute to the effects shown here. Such correlations would complicate emulations based on year-over-year yields but would not necessarily bias them. See Supplemental Figures SX-SX for other crops, models, and locations.

We therefore explicitly test the assumption that distributional changes are not consequential for climatological mean yields: in Section 4.2, we confirm that an emulator trained on the GGCMI Phase II dataset can successfully reproduce yield changes under a full climate model projection.

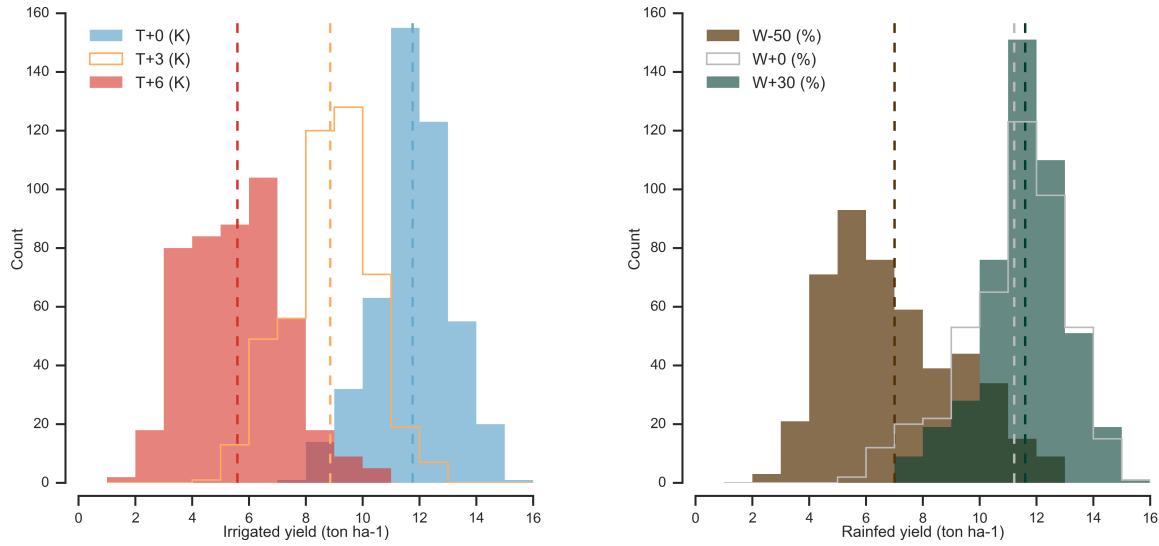

Figure 2. Example showing results of increased crop yield sensitivity to year-over-year climate variations under climate stress. Yield distributions are from examples of Figure 1, top row, of maize in Iowa, (**left**) for irrigated maize in scenarios of altered temperature and (**right**) for rainfed maize in scenarios of altered precipitation. Because yield sensitivities rise under strong warming or drying, distributions of year-over-year crop yields widen in T+6 and P-50% scenarios relative to present-day simulations, even though all input climate timeseries have identical variance for temperature. Note: precipitation changes have different variance since the perturbations are fractional.

Note that even though distributions of climate variables are unchanged in the GGCMI Phase II simulations, the spread in annual yields still becomes wider in highly impacted climate states, because of the nonlinearity of yield responses (Figure 2). In the GGCMI Phase II dataset, all crops except rice show greater year-to-year yield variance in conditions of extreme climate stress. (Rice is typically irrigated and experiences no water stress.) Increased variance has been noted in previous studies.

5 For example, Urban et al. (2012) used statistical models trained on present-day yields to find a projected future increase in yield variance of U.S. maize of 20% per degree K temperature rise. While the authors do not diagnose a specific cause of that increase, they discuss multiple potential mechanisms, including nonlinearity in responses.

3 Emulation

Emulation involves fitting individual regression models from GGCMI Phase II output for each crop and model and 0.5 degree geographic pixel; the regressors are the applied perturbations in CO₂, temperature, water, and nitrogen (CTWN). We discuss here largely emulations of climatological mean crop yield with no growing season adaptation (A0 scenarios), but note that any output of the crop models can potentially be emulated. We provide separate emulations of not only irrigated and rainfed yields but also applied irrigation water (pirrww in mm yr⁻¹, see (Franke et al., 2019)) in both the A0 and A1 growing season, meaning that each model and crop combination results in six sets of regressions. (See Supplemental Material SXX for more information on additional cases not shown.)

3.1 Statistical model

For the statistical model of crop yields as a function of CTWN, we choose a relatively simple parametric model with a 3rd-order polynomial basis function. If the climatological mean response is relatively smooth, then a simpler form provides a reasonable fit that allows for some interpretation of resultant parameter weights. A relatively simple parametric form also allows fast 5 model emulation at the grid cell level, rather than requiring spatial aggregation. Emulating at the grid cell level preserves the spatial resolution of the parent models, and means that emulators indirectly includes any yield response to geographically distributed factors such as soil type, insolation, and the baseline climate. The 3rd-order polynomial CTWN model contains 34 terms (Equation 1), since the N^3 term is omitted, as it cannot be fitted in a training set sampling only three nitrogen levels. To facilitate comparing emulators parameter-by-parameter, we hold this functional form constant in space, across all crops, and 10 models, other than several necessary distinctions: regressions for irrigated crops do not contain W terms, and regressions for models that do not sample the nitrogen levels omit the N terms.

$$\begin{aligned}
 Y = & K_1 & (1) \\
 & + K_2 C + K_3 T + K_4 W + K_5 N + K_6 C^2 \\
 & + K_7 T^2 + K_8 W^2 + K_9 N^2 + K_{10} CW \\
 & + K_{11} CN + K_{12} TW + K_{13} TN + K_{14} WN \\
 & + K_{15} CT + K_{16} T^3 + K_{17} W^3 + K_{18} C^3 + K_* N^3 \\
 & + K_{19} TWN + K_{20} T^2 W + K_{21} W^2 + K_{22} W^2 N \\
 & + K_{23} CWN + K_{24} CTN + K_{25} CTW + K_{26} N^2 C \\
 & + K_{27} N^2 T + K_{28} N^2 W + K_{29} T^2 N + K_{30} T^2 C \\
 & + K_{31} W^2 C + K_{32} C^2 W + K_{33} C^2 T + K_{34} C^2 N
 \end{aligned}$$

Results shown throughout the paper use this full specification, but we also investigate (in Section 3.2 below) whether some terms can be dropped without significant reduction in emulator fidelity. In general, both higher-order and interaction terms are expected to be important for representing crop yields. Higher order terms are needed because crop yield responses to weather are well-documented to be nonlinear: e.g. Schlenker and Roberts (2009) for T perturbations and He et al. (2016) for W 25 (precipitation). Interaction terms are needed since the yield response is expected to depend on interactions between the major inputs. For example, Lobell and Field (2007) and Tebaldi and Lobell (2008) showed that in real-world yields (with C and N fixed), the joint distribution in T and W is needed to explain observed yield variance. Other observation-based studies have shown the importance of the interaction between W and N (e.g. Aulakh and Malhi, 2005), and between N and C (Osaki et al., 1992; Nakamura et al., 1997).

We do not focus in this study on comparing other functional forms or non-parametric models. Some prior studies have used 30 other statistical specifications in crop model emulation: for example, Blanc and Sultan (2015) and Blanc (2017) use a 39 term fractional polynomial and “borrow information across space” by fitting grid points simultaneously across soil region in a panel

regression. The GGCMI Phase II dataset allows fitting our simple 3rd order polynomial form independently at each grid cell while still providing a satisfactory emulation for all models and crops. (See Section 4 for evaluation of the fidelity of emulators constructed with Equation 1.)

3.2 Feature importance and reduced statistical model

5 Because a simpler statistical model may improve the interpretability of its parameter weights, we also develop a reduced version that is satisfactory for most models and crops (Equation 2). To identify terms that can be omitted, we apply a feature selection cross-validation process in which terms in the polynomial are tested for importance. Higher-order and interaction terms are successively added to the regression model, and in each case we calculate an aggregate mean absolute error (weighted by currently cultivated area) and eliminate those terms that do not contribute significantly to reducing error. The procedure is
10 illustrated in Figure 3. We develop our reduced statistical model by considering yields over currently cultivated land in three models: two that provided the complete set of 672 rainfed simulations, i.e. without the W_∞ simulations, (pDSSAT, EPIC-TAMU), and one that provided the smallest training set (121 input combinations, PEPIC). Although models exhibit different absolute levels of error, all three agree remarkably well on feature importance, i.e. on which terms reduce error and which provide no predictive benefit. (Agreement means that line slopes match in Figure 3.)

$$15 \quad Y = K_1 \quad (2)$$

$$\begin{aligned} & + K_2 C + K_3 T + K_4 W + K_5 N + K_6 C^2 \\ & + K_7 T^2 + K_8 W^2 + K_9 N^2 + K_{10} CW \\ & + K_{11} CN + K_{12} TW + K_{13} TN + K_{14} WN \\ & + K_a CT + K_{15} T^3 + K_{16} W^3 + K_b C^3 + K_c N^3 \\ 20 & + K_{17} TWN + K_{18} T^2 W + K_{19} W^2 + K_{20} W^2 N \\ & + K_d CWN + K_e CTN + K_f CTW + K_{21} N^2 C \\ & + K_{22} N^2 T + K_{23} N^2 W + K_g T^2 N + K_h T^2 C \\ & + K_i W^2 C + K_j C^2 W + K_k C^2 T + K_l C^2 N \end{aligned}$$

Results of the feature selection process suggest that 11 terms can be omitted with negligible impact on emulator fidelity,
25 producing the 23-term statistical model of Equation 2. The eliminated terms include many of those in C: the cubic; the CT, CTN, CTW, and CWN interaction terms; and all higher order interaction terms in C. Finally, we eliminate one 2nd-order interaction term in W and two in T. Implications of this choice include that nitrogen interactions are complex and important, and that water interaction effects are more nonlinear than those in temperature. Note that some terms that did not reduce the aggregate error must still be included if a higher order version of that term provides benefit: for example, including the T^3 term
30 requires also retaining T^2 and T terms. The reduced-form emulator is acceptable across currently cultivated land for all model and crop combinations other than JULES soy and spring wheat and PROMET soy and rice. These cases involve yield responses that benefit strongly from inclusion of higher order carbon interaction terms. Additional terms in the statistical model also help

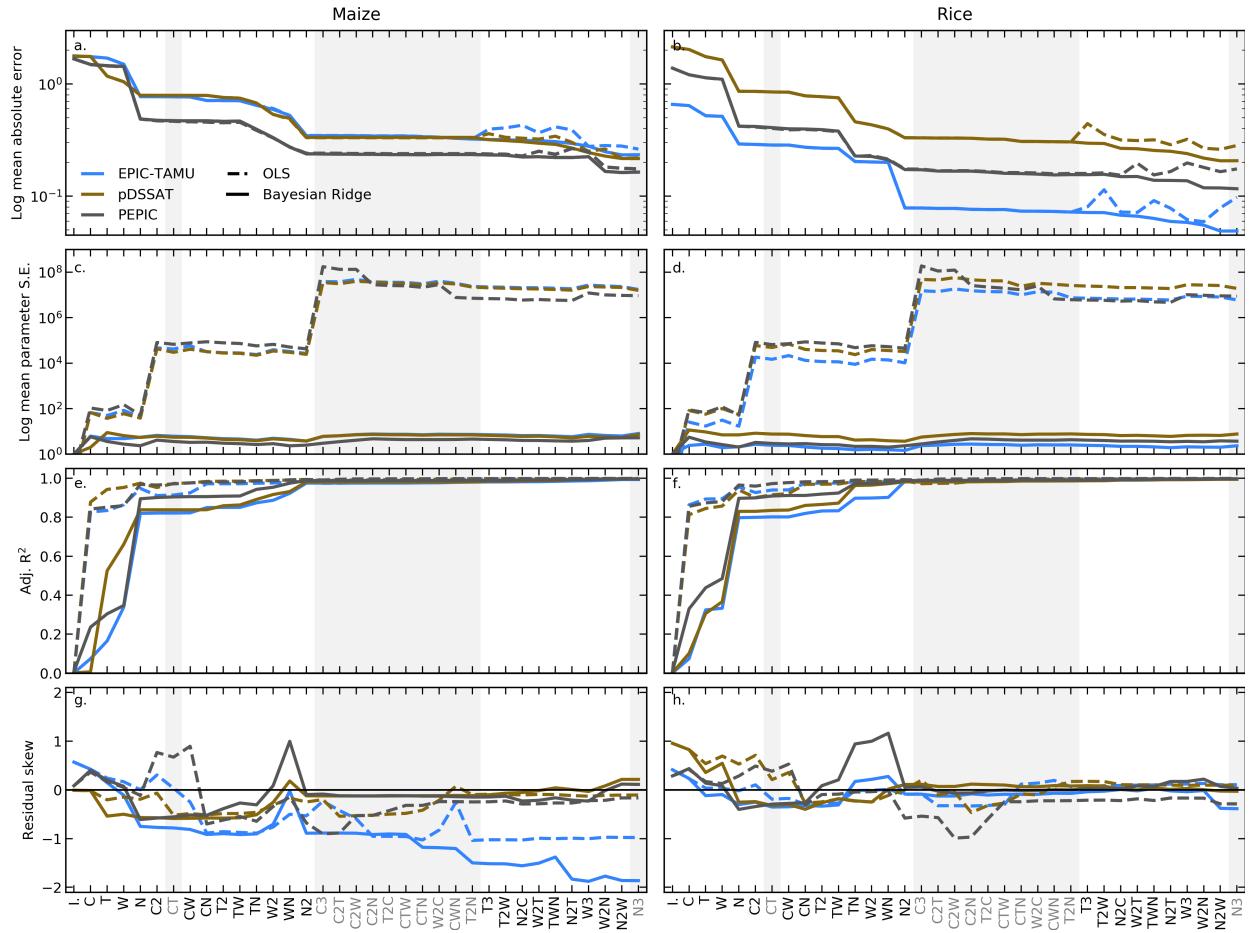

Figure 3. Illustration of results from the polynomial feature selection process for three different crop models (colors), for all grid cells with more than 1000 ha cultivated for maize (**left**) and rice (**right**). Solid lines are Bayesian Ridge regression results and dashed lines those for standard OLS. Rows show four metrics of fit quality and x axes the terms successively tested in the statistical model, sequentially added to the model in order from left to right. Terms that do not reduce the aggregate error are marked in gray and are not included in the final model. **a & b:** log mean absolute error between emulated yield and simulated values calculated with a three fold cross validation process, where the emulator is trained on two thirds of the data and predicts the remaining third. **c & d:** log mean standard parameter error. The Bayesian Ridge method strongly reduces parameter error and results in more stable estimates. **e & f:** adjusted R^2 score for the fit at each model specification. **g & h:** distribution of the residuals. Skewness is low at the high model specifications tested in all model cases other than EPIC-TAMU maize.

emulation in some geographic locations outside of currently cultivated regions, where yield responses are again complex. (See Supplemental Material Section XX for evaluation of the fidelity of emulators constructed with Equation 2 and for more details on JULES and PROMET.)

3.3 Model fitting

To fit the parameters K , we use a Bayesian Ridge regularization method (MacKay, 1991) rather than standard ordinary least squares (OLS). The Bayesian Ridge method reduces volatility in parameter estimates when the sampling is sparse, by weighting parameter estimates towards zero, allowing the use of a consistent functional form across all models and locations. The choice

5 slightly reduces mean absolute error for some of the high-order interaction terms in the model (Figure 3, top row) but drastically reduces standard parameter error in the model by stabilizing the estimates (Figure 3, third row). The estimation method scores relatively lower on adjusted R^2 for the simplest parameter specifications, but reaches parity with the OLS at the number of terms included in this study. We use adjusted R^2 as a metric because additional terms are penalized (Equation 3, where n is the number of samples and k is the number of features):

$$10 \quad R_{adj}^2 = 1 - \frac{(n - 1) \cdot (1 - R^2)}{n - k} \quad (3)$$

We use the implementation of the Bayesian Ridge estimator from the scikit-learn package in Python (Pedregosa et al., 2011).

An additional diagnostic of fit quality is the distribution of residuals: normally or near-normally distributed residuals imply that errors around the fit are random and unbiased. When fitting Equation 1 to the GGCMI Phase II dataset, the distribution of the residuals depends on the number of features included in the regression, the method for estimating the parameters, and the target distribution in the training set. The residuals are only normally distributed ($pvalue > 0.05$ in the Shapiro–Wilk test) for a single model, PEPIC, for any specification tested here, but their skew is relatively small except in a single case, EPIC-TAMU maize (Figure 3, fourth row). While including higher-order terms in the statistical model generally reduces residual skew, for EPIC-TAMU maize it increases skew instead, but also reduces the error in cross-validation, which we consider more important in the context of emulation. The residual distribution suggests that projections using the emulator for EPIC-TAMU maize will tend to be biased high, but the overall magnitude of the errors will be below 2% of yield changes.

4 Emulator evaluation

In this section we show illustrations of GGCMI model yield responses to climate perturbations and evaluate the ability of our emulators to reproduce them. Model emulation with the parametric method used here requires that crop yield responses be sufficiently smooth and continuous to allow fitting with a relatively simple functional form; this condition largely holds in the GGCMI Phase II simulations. In this section we evaluate metrics of emulator performance for the 34-term polynomial of Equation 1; see Supplemental Materials Section XX for analogous evaluation of the 23-term polynomial of Equation 2. We find that emulation errors – discrepancies between emulation and simulation – are generally small, especially when compared to the differences across crop models or to projected yield changes. Emulation errors become problematic only in certain, limited geographic locations, usually where crops are not currently grown. We also separately assess the emulator’s ability to reproduce crop yields in a more realistic future simulation driven by a climate model projection, and find that the effects of changes in variability not included in the GGCMI Phase II training set are generalaly negligible relative to the effects of mean changes.

4.1 Yield response

Crop yields show strong spatial differentiation across geographic regions, and emulators are able to readily reproduce these. Figure 4 illustrates the spatial yield pattern under current climate for one crop and model (maize in LPJmL). Absolute emulation errors are low – 99.8% of grid cells have errors below 0.5 tons ha^{-1} – but emulation errors as a percentage of baseline yield can be large in areas with low potential yield and no current cultivation in the real world (e.g. the Sahara, Patagonia). These regions are not currently viable for agriculture and may never become viable even under extreme climate change. Emulator spatial skill varies across models and crops, with maize being the quantitatively easiest to emulate across all models and locations.

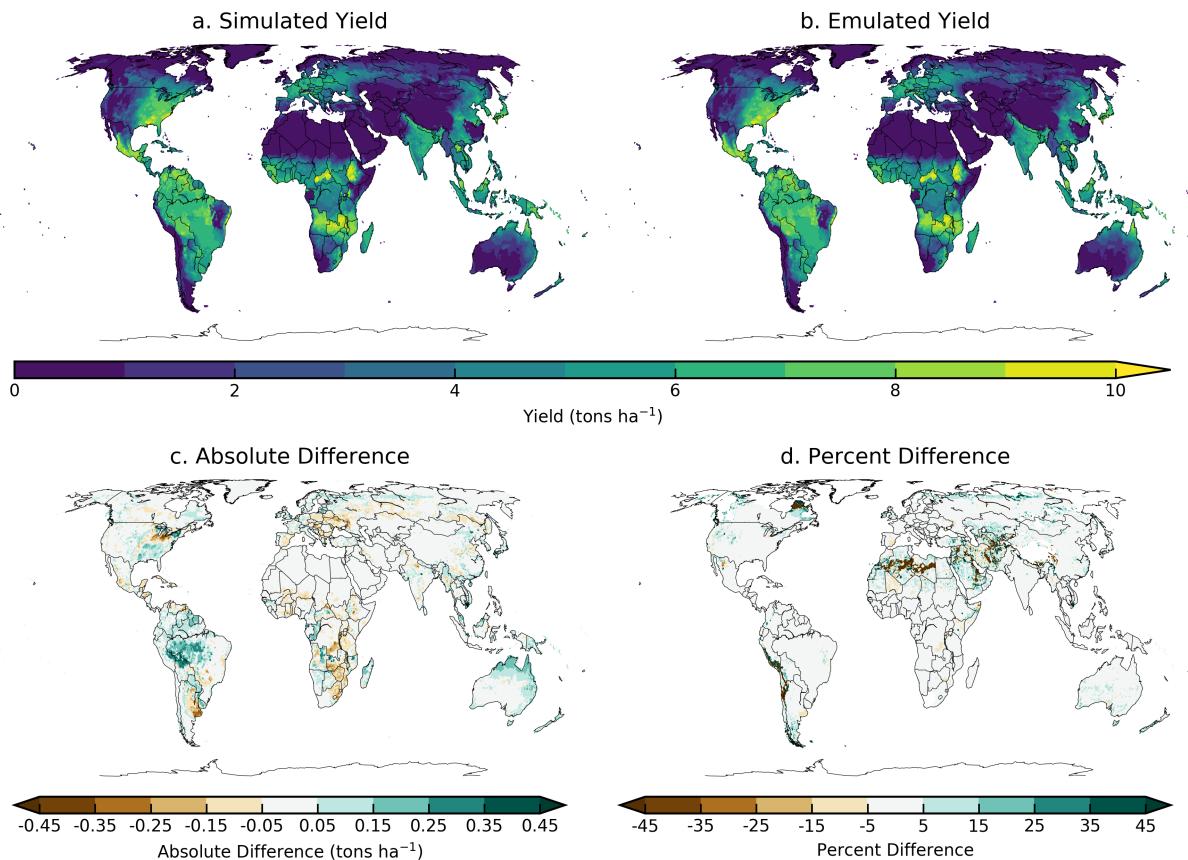

Figure 4. Illustration of spatial pattern in baseline yield successfully captured by the emulator: simulated (a.) and emulated (b.) yield under historical (1981–2010) conditions for rainfed maize from the LPJmL model. Absolute yield differences (c.) are less than 0.5 ton ha^{-1} in almost all (99.8%) grid cells across the globe. Percent difference (from simulated baseline, d.) is below 5% in most (75%) grid cells currently cultivated in the real world. Approximately 7% of all grid cells, but only 3% of currently cultivated grid cell, have emulated yields that differ from the baseline simulation by more than 20%. Notable exceptions include areas with very low simulated baseline yield, including for example the Sahara, the Andes, and northern Quebec. Percent error weighted by cultivation area globally is essentially zero (see also Table 3). Performance varies by crop and model. See Supplemental Figures XX–XX for more examples.

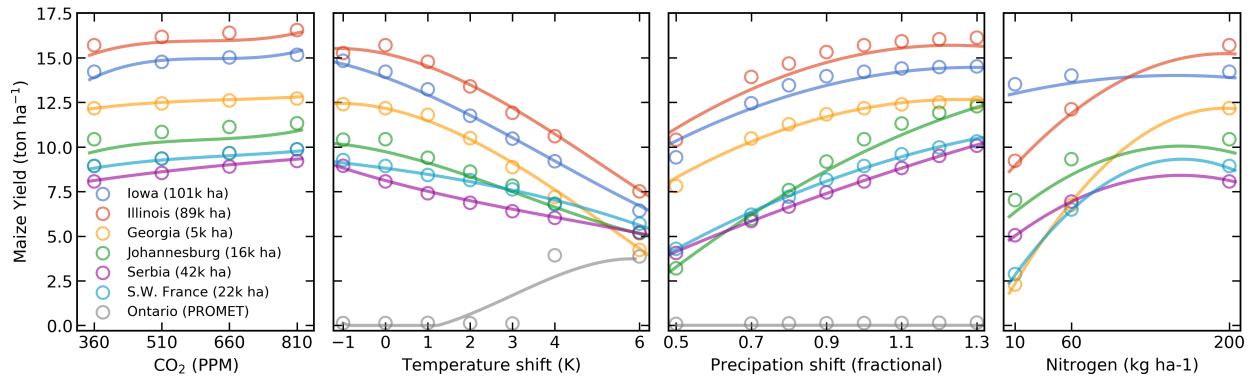

Figure 5. Illustration of spatial variations in yield response, which are successfully captured by the emulator. Panels show simulations (points) and emulations (lines) of rainfed maize in the pDSSAT model in six example locations selected to represent high-cultivation areas around the globe. Legend includes hectares cultivated in each selected grid cell. Each panel shows variation along a single variable, with others held at baseline values. Dots show climatological mean yields and lines the results of the full 4D emulator of Equation 1. In general the climatological response surface is sufficiently smooth that it can be represented within the sampled variable space by the simple polynomial used in this work. In some cases extrapolation would produce misleading results, and the emulator fails in conditions where yield response changes abruptly. Failure is illustrated here by rainfed maize in north-central Ontario for the PROMET model (in gray), which shows present-day yields of zero rising abruptly if temperature warms by 4 degrees.

Yield responses to the four main drivers considered here (C, T, W, and N) are also quite diverse across locations, crops, and models, but in nearly all cases the local climatological mean responses are smooth enough to permit emulation with the functional form used here. Figure 5 illustrates geographic diversity of responses within a single crop and model, for rainfed maize in pDSSAT. While CO₂ responses (in $\text{ton ha}^{-1}/\text{ppm}$) are quite similar, precipitation response is stronger in more arid locations and nitrogen responses appear strongly soil-dependent. The heterogeneity in response supports the choice of emulating at the grid cell level. In regions with current cultivation, yields evolve smoothly across the space sampled, and the polynomial fit captures the climatological-mean response to perturbations well. Emulators do perform poorly in a few regions that involve discontinuous or irregular yield responses. Poor performance is illustrated here with maize from the PROMET model in northern Canada, which is considered too cold for maize at present (0 ton ha^{-1} yield), but which shows an abrupt rise to moderate yields once temperature rises by 4 degrees. Under these conditions, the 3rd order polynomial cannot fit the response, and errors are high. See Section 4.2 for additional discussion.

Crop yield responses in all models generally follow similar functional forms at any given location, though with a spread in magnitude (Figure 6, which shows rainfed maize in northern Iowa in a selection of GGCMI models). Absolute yield differences between models can be substantial because models are uncalibrated in some cases. In general, models are most similar in their responses to temperature perturbations, and least similar to changes in CO₂. That is, CO₂ fertilization effects *within* a single model are consistent across locations, but CO₂ effects differ strongly *across* models.

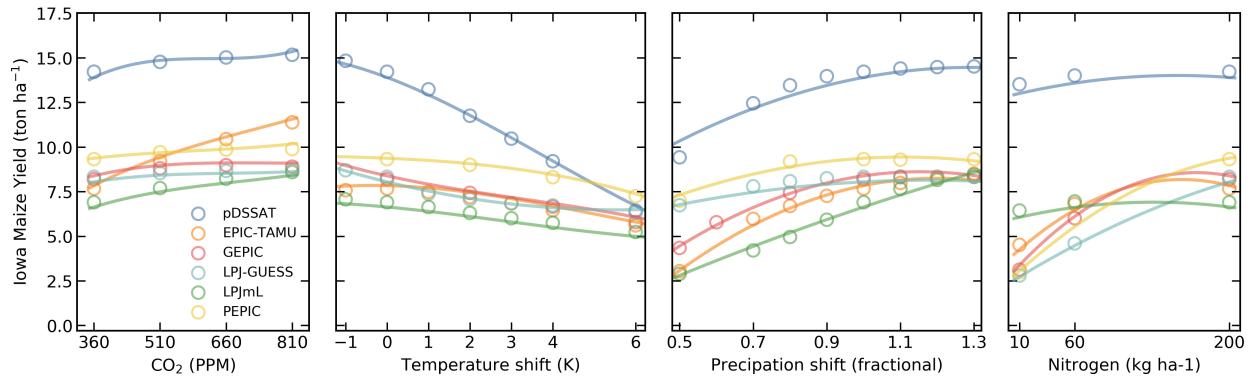

Figure 6. Illustration of variations in yield response across models, again successfully captured by the emulator. Panels show simulations and emulations from six representative GGCMI models for rainfed maize in the same Iowa grid cell shown in Figure 5, with the same plot conventions. Three models (PROMET, JULES, and CARAIB) that do not simulate the nitrogen dimension are omitted for clarity. Models are uncalibrated, producing spread in absolute yields. While most model responses can readily emulate with a simple polynomial, some response surfaces diverge slightly from the polynomial form, producing emulation error (e.g. pDSSAT here, for water), but resulting error generally remains small relative to differences across models.

Note that while the nitrogen dimension is important, it is also the most troublesome to emulate in the GGCMI Phase II experiment because of its limited sampling. The GGCMI Phase II protocol specified only three nitrogen levels ($10, 60$ and $200 \text{ kg N y}^{-1} \text{ ha}^{-1}$), so a third-order fit would be over-determined but a second-order fit can result in potentially unphysical results.

5 Steep and nonlinear declines in yield with lower nitrogen levels mean that some regressions imply a peak in yield between the 100 and $200 \text{ kg N y}^{-1} \text{ ha}^{-1}$ levels (Figure 6, right). While reduced yields under high nitrogen levels are physically possible and could reflect over-application at particular times in the growing period, they are implausible at the magnitude shown here and likely an artifact of the fit. The Bayesian Ridge estimator mitigates the ‘peak-decline effect’ in the nitrogen dimension relative to ordinary least squares, but does not entirely remove it. The polynomial fit also cannot capture the well-documented saturation effect of nitrogen application (e.g. Ingestad, 1977) as accurately as would be possible with a non-parametric model.

10 4.2 Emulator performance metrics

Our emulators collectively consist of nearly 3 million individual regressions, so developing concise performance metrics poses a challenge. No general agreed-upon criteria exist for defining an acceptable crop model emulator, so we present two different metrics below, one relatively loose and one more stringent. Both metrics assess the ability of the emulator to reproduce simulated crop yields in the GGCMI Phase II experiment. In this section we show only results from emulators based on the 34-term Equation 1; see Supplemental Material Section XX for analogous assessment of emulators based on the 23-term Equation 2.

15 *1. Normalized error.* We take as our first metric what we term the “normalized error”, which compares the fidelity of an emulator to the inter-model spread. For a multi-model comparison exercise like GGCMI Phase II, a reasonable though loose emulator criterion is that its errors be small relative to intermodel differences. The normalized error e is defined separately

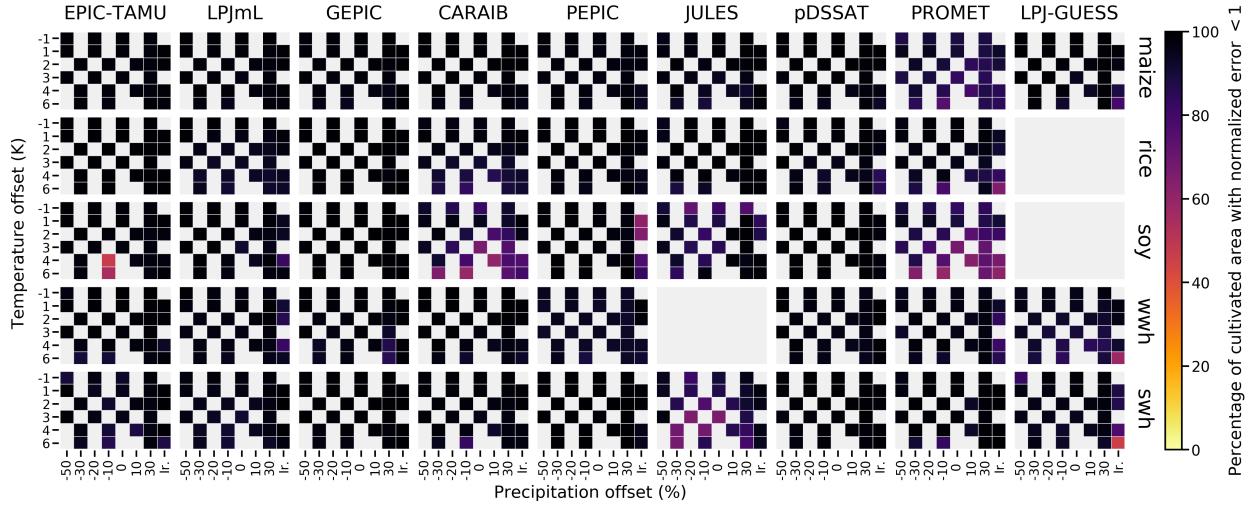

Figure 7. Assessment of emulator performance over currently cultivated areas based on normalized error (Equations 5). We show performance of all 9 models emulated, over all crops and all sampled T and W inputs (“ir.” indicates the irrigated W_∞ setting), but with CO_2 and nitrogen held fixed at baseline values. Large columns are crops and large rows models; squares within are T, W scenario pairs. Colors denote the fraction of currently cultivated hectares (“area frac”) for each crop with normalized area e less than 1 indicating the the error between the emulation and simulation less than one standard deviation of the ensemble simulation spread. Of the possible 63 scenarios at a single CO_2 and N value, we consider only those for which all 9 (8 for rice, soybean, and winter wheat) models submitted data (Figure S1) so the model ensemble standard deviation can be calculated uniformly in each case. JULES did not simulate winter wheat and LPJ-GUESS did not simulate rice and soybean. Emulator performance is generally satisfactory, with some exceptions. Emulator failures (significant areas of poor performance) occur for individual crop-model combinations, with performance generally degrading for colder and wetter scenarios.

for each C,T,W,N scenario s as the difference between emulated and simulated fractional yield changes, normalized by the standard deviation in simulated changes across all models:

$$e_s = \frac{F_{em, s} - F_{sim, s}}{\sigma_{sim, s}} \quad (4)$$

where F is the fractional change in yields Y between scenario s and baseline b :

$$F_s = \frac{Y_s - Y_b}{Y_b} \quad (5)$$

- 5 We calculate the mean error for each grid cell, model, and crop in each C,T,W,N scenario by comparing emulated and simulated yields. A normalized error $e < 1$ means that any deviation of the emulation from the simulation is less than 1 standard deviation of the inter-model spread.

Evaluation of this metric implies that GGCMI Phase II emulators are generally satisfactory. Emulator performance is illustrated in Figure 7, which shows all models and crops crops over currently cultivated area. Over all crops and models, the

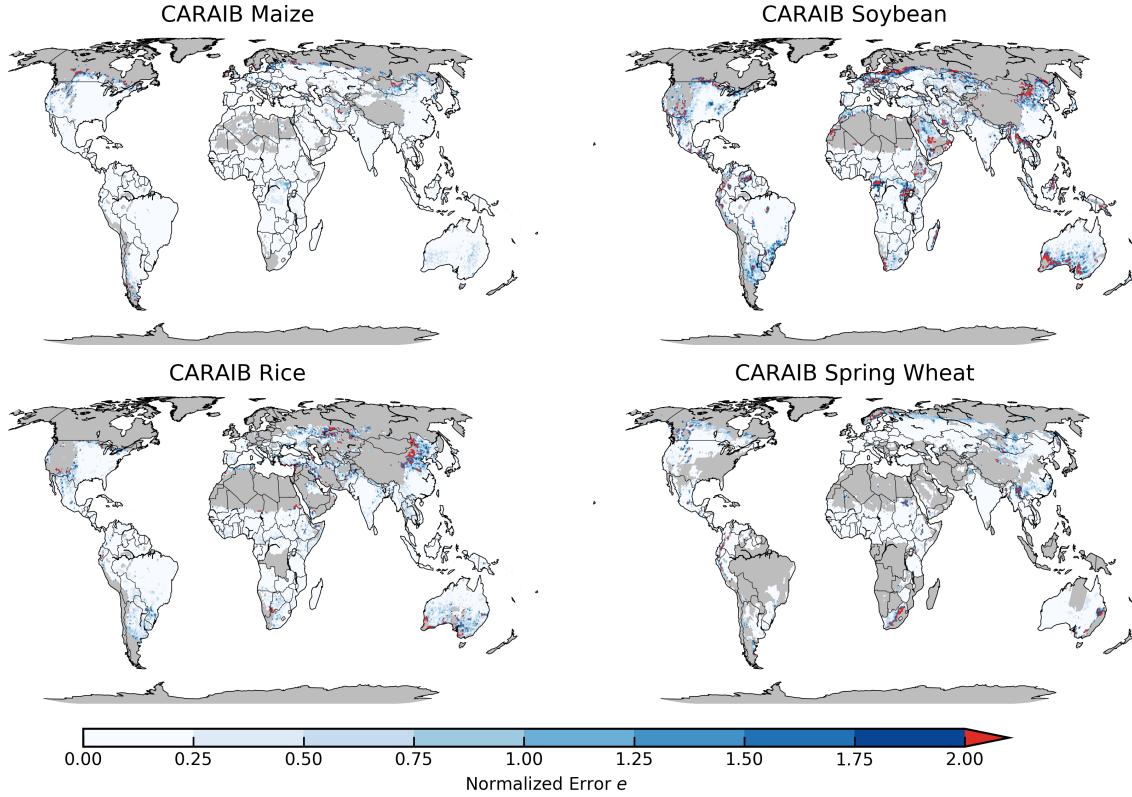

Figure 8. Illustration of our first test of emulator performance, applied to the CARAIB model for the T+4 scenario for rainfed crops. Colors indicate the normalized emulator error e , where $e > 1$ means that emulator error exceeds the multi-model standard deviation. For consistency, we show e only for geographic areas simulated by at least six models and where baseline yields are greater than 0.5 ton ha^{-1} . Emulator performance is generally good relative to model spread in areas where crops are currently cultivated (compare to Figure S2-S3) and in temperate zones in general; emulation issues occur primarily in marginal areas with low yield potentials.

average normalized error $e < 1$ over 95% of currently cultivated area. For maize, the most tractable crop to emulate, all 9 models return $e < 1$ over 97% of currently cultivated area. Only three crop-model combinations are problematic, returning $e < 1$ over less than 90% of cultivated area: PROMET and CARAIB for soybeans (79% and 83%), and JULES for spring wheat (85%). Misfits typically occur when models show strong discontinuities in yield response (as shown in Figure 5), or when
 5 carbon fertilization gains interact nonlinearly with changes in temperature or water. Including higher-order C terms helps in the latter case but does not reduce emulator errors to zero. See Supplemental Figures SXX-SXX for examples of worst-case emulator failures.

While Figure 7 shows only currently cultivated land, performance can be worse in locations where crops are not currently cultivated, or on marginal lands where current potential yields are low. (In general, emulator performance is poor anywhere
 10 that models show steep yield changes once some threshold has been reached, whether these are abrupt gains or complete crop failures.) Figure 8 illustrates this effect for CARAIB in the T+4 scenario, showing normalized error over all simulated area

with non-zero baseline yield and at least 6 models providing simulations. CARAIB emulator performance is generally good where crops are grown but can be poor ($e > 2$) in arid or mountainous zones, e.g. the edges of the Sahara, Inner Mongolia, South Africa and Southern Australia. (See Supplemental Material Section XX for analogous figures for all crop and model combinations and for multiple climate perturbations.) Note that the choice of statistical model for emulation involves a trade-off in the spatial pattern of errors: adding terms to the statistical model increases emulator fidelity in problematic “fringe” areas where crops are currently not cultivated, but reduces it slightly over high-yield areas. For example, CARAIB maize emulators have normalized error $e < 1$ over 98.8% of currently cultivated land with the reduced 23-term Equation 2 but only 98.5% with the 34-term Equation 1. Over simulated uncultivated land, CARAIB maize emulators have $e < 1$ for only 88.7% of area with the reduced Equation 2 but 93.7% with the full Equation 1.

10 Note that the normalized error assessment is relatively forgiving for several reasons. First, it is an in-sample validation, with the emulation evaluated against the simulations actually used to train the emulator. Had we used a spline interpolation, the error would necessarily be zero. Second, the metric scales emulator fidelity not by the magnitude of yield changes in the evaluated model but by the spread in yield changes across models. The normalized error e for a given model then depends on the particular suite of other models considered in the intercomparison exercise. The rationale for the choice is to relate the
15 fidelity of the emulation to the true uncertainty, which we take as the multi-model spread, but the metric then has the property that where models differ more widely, the standard for emulators becomes less stringent, and vice versa. In GGCMI Phase II the effect is manifested in the higher normalized errors for soybeans across all models, which result not because soybean yields are difficult to emulate but because models agree more closely on yield changes for soybeans than for the other crops.

2. *Out-of-sample validation.* We provide a second, more stringent test of emulator performance via a cross validation (also
20 termed an out-of-sample validation). In this test the GGCMI Phase II dataset is split randomly into two parts, with 90% of the data used to train the model and the held-out 10% used to test the fidelity of the resulting emulator. We calculate the root mean square error (RMSE) between emulated (predicted) and actual simulated values across the test set, repeat the process twice, and average the results of the two splits. As a last step, we normalize the RMSE in each grid cell by dividing by the simulated yield change.

25 The resulting error metric is generally low. Table 3 shows the yield-change-normalized RMSE for rainfed crops in all models over currently cultivated land, both in selected major producing regions and in the global average. (We include all simulations in CTWN space and take the average error value.) Mean grid cell RMSE is below 5% of yield changes in all cases, or in absolute terms less than 0.2 ton ha⁻¹ for all except JULES soy, which is 0.36 ton ha⁻¹ in the global mean. For irrigated crops, absolute emulator errors are generally lower, but since irrigated crops experience lower yield changes the
30 fractional errors are similar. See Supplemental Material Section XX for maps of cross validation RMSE for each crop and model.

Note that this metric is relatively simple and may be over conservative. The randomized sampling protocol for dividing training and test sets can mean that a training set omits edge simulations at the highest or lowest value of CTWN space. The test prediction then involves extrapolating out of the training set range (e.g. predicting a T+6 case when the training set extends

Table 3. RMSE of emulator replication of simulated yields of rainfed crops, stated as a percentage of simulated yield change. Values are the mean grid cell error as a percentage of simulated yield change, over all currently cultivated grid cells weighted by cultivation area, for selected major regions (NA: North America, SA: South America). For comparison, global mean values are show in parentheses. Errors are calculated using the 90-10 cross validation scheme described in text, with the model trained on 90% of the data and validated on the held-out 10% (repeated twice). All fits are made with the Bayesian Ridge method; for context we mark with * those cases where the Bayesian Ridge is required because the OLS linear model fails (e.g. PEPIC, which has the lowest number of samples at n=121).

Model	NA Maize %	SA Soybean %	SE Asian Rice %	NA S. Wheat %	European W. Wheat %
CARAIB	0.7 (0.9)	2.4 (2.4)	2.4 (2.4)	1.3 (1.4)	2.7 (1.9)
EPIC-TAMU	2.4 (1.8)	1.8 (2.6)	1.6 (1.6)	1.8 (1.9)*	1.1 (1.1)
JULES	2.6 (2.6)	4.6 (4.0)	1.6 (1.7)	2.0 (2.2)	NA
GEPIC	2.1 (2.4)	1.0 (1.2)	2.0 (2.1)	3.7 (3.3)	4.0 (2.9)
LPJ-GUESS	1.0 (1.1)	NA	NA	1.0 (1.3)	1.0 (1.2)
LPJmL	1.8 (1.8)	1.1 (1.3)	1.2 (1.1)	0.8 (1.1)	1.5 (1.3)
pDSSAT	1.9 (1.7)	1.2 (1.1)	1.7 (1.6)	1.1 (1.3)	1.4 (1.5)
PROMET	3.4 (2.7)*	2.0 (2.7)*	2.1 (1.8)*	4.3 (3.7)*	4.6 (3.4)*
PEPIC	1.8 (1.8)*	1.4 (1.9)*	1.4 (1.4)*	2.3 (2.3)*	4.9 (2.9)*

only to T+4), an improper use of an emulator. Values would be lower under a different sampling strategy (e.g. “leave-one-out”). For additional discussion of more detailed potential evaluation metrics, see e.g. Castruccio et al. (2014).

4.3 Emulation of realistic climate projections

Finally, we test the ability of an emulator based on the GGCMI Phase II perturbed mean training set to reproduce the response of a crop model driven by a realistic evolving climate scenario. The goal is to assess whether effects of future changes in temperature and precipitation distributions are strong enough to compromise a GGCMI-based emulator. We first drive the LPJmL crop model (representative of GGCMI model) with climate model output under the high-end RCP 8.5 scenario (Supplemental Figure XX). We choose for this purpose the a climate model (HadGEM2-ES) with relatively high change in growing-season temperature variability relative to other models in the Coupled Model Intercomparison Project Phase 5 (CMIP-5) archive (Jones et al., 2011; Martin et al., 2011). We then drive the LPJmL emulator with the HadGEM2-ES yearly-growing season anomalies, and evaluate how well the resulting emulated yields reproduce those simulated under the full climate scenario. The comparison suggests that globally, the results of future distributional shifts on climatological yields are negligible relative to the effects of mean changes (Figure 9). In the LPJmL example of Figure 9, emulated and simulated global production in the last decade of the simulation are identical to within 1.5% for all crops. The emulator also reproduces decadal variation in yields, which is especially strong in spring wheat that is grown in northern latitudes, and even captures much of the residual year-over-year yield variability. (R^2 of emulated vs. simulated annual yield anomalies relative to the 10-year running mean is 0.8 for spring wheat and ~0.3 for all other crops).

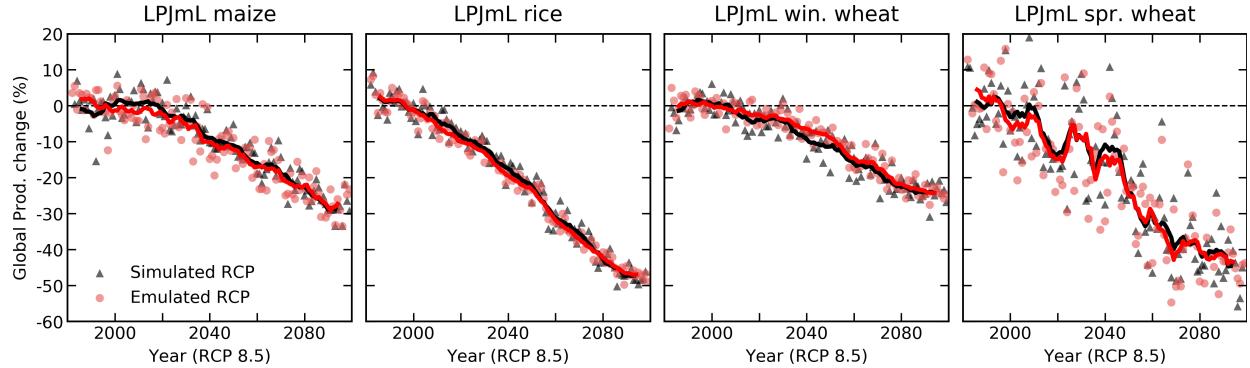

Figure 9. Test of emulator performance in reproducing yield simulations made with a realistic climate projection. Panels show simulated (black) and emulated (red) global production for four crops from the LPJmL model, driven with temperature and precipitation outputs from the HadGEM2-ES climate model for the RCP8.5 scenario. In both cases nitrogen and CO₂ are held fixed, at 200 kg ha⁻¹ and 360 ppm. Points show yearly global production change from the 1981–2010 baseline, and lines show a 10-year running mean. See text for discussion of relating the HadGEM2-ES temperature timeseries to the appropriate offset used in emulation. Emulators trained on uniform climatological offsets reproduce well the simulated production response under a realistic climate scenario: yields at end of century match to within 1.5%.

Distributional effects might be expected to be stronger at high latitudes, because temperature and precipitation variability are larger there, so that changes in variability can be correspondingly more important. Most crops however (spring wheat, winter wheat, and maize) show no emulator bias that grows with latitude. Rice is the exception: north of 30 degrees latitude (where only 20% of global rice is cultivated), the climatological-mean emulator underestimates losses under climate change (by 2100, 5 losses of 39% vs. 50% in simulations), leaving a 9% low bias in emulated end-of-century rice yields (Supplemental Figure XX).

It is worth noting two complications involved in comparing emulated to simulated yields under a realistic climate change scenario, as in Figure 9. First, it is not trivial to choose how to relate temperature or precipitation in the evolving climate scenario to the T and P offsets used as regressors to the emulator. Using growing-season mean temperature can lead to complications 10 if crop models assume that growing season lengths shift under climate change. For consistency, we match the temperature changes in the climate scenario to their equivalent emulator regressors by calculating means over the fixed baseline growing season. The choice of growing season ensures that the emulation is appropriately matched to the simulation. Second, while the emulator outputs an estimated yield change, the baseline from which that yield change is calculated will be different between simulation and emulation, because the historical climate timeseries are not identical. For example, the baseline (1981–2010) 15 yield of winter wheat simulated by LPJmL using the AgMERRA timeseries as part of GGCMI Phase II is 7% lower than that simulated using the HadGEM2-ES timeseries. To minimize the effects of different historical climate assumptions, we drive the emulator with the anomaly of the climate scenario from its own 1981–2010 mean. Bias in the historical climate timeseries could in theory produce discrepancies between emulated and simulated yield changes because of the nonlinearities discussed in Section 2.2, but appear to play little role in the LPJmL comparison of Figure 9.

5 Emulator results and products

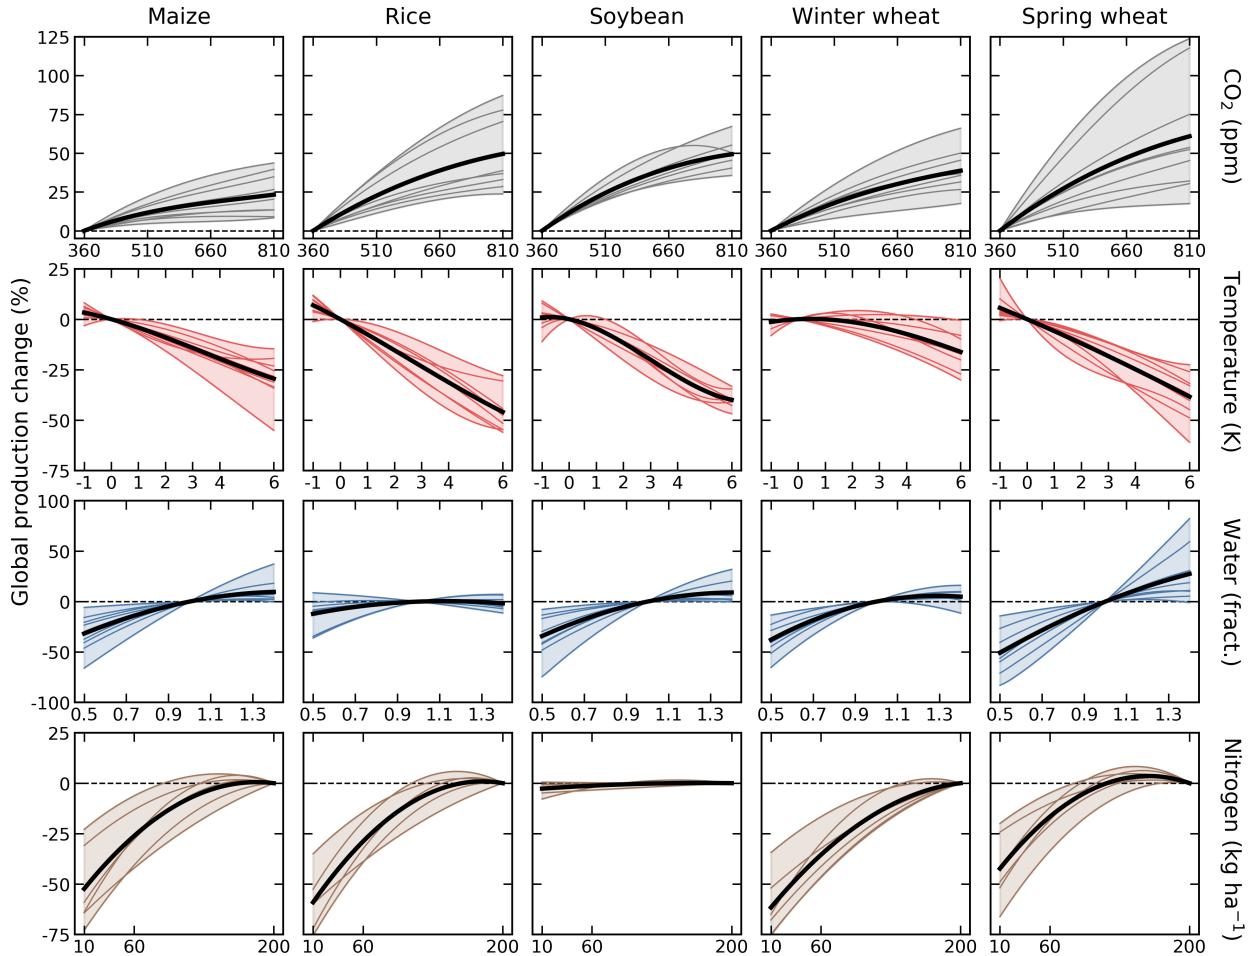

Figure 10. Emulated global damage functions for the five GCCMI Phase II crops over the four dimensions varied: CO₂, temperature, water, and nitrogen. Black line shows the multi-model mean and shaded area and colored lines the individual models. Each panel shows response to one covariate, with all others held constant at baseline values. Damages are reported as percent change in global production over currently cultivated land relative to the 1981-2010 baseline. Note that y-axis ranges are not uniform. As expected, the N response is smallest in soybeans, which are efficient nitrogen fixers, and the CO₂ response smallest in maize, which is a C4 crop. Spring wheat has the largest intermodel spread and soybeans the smallest. For an analogous figure identifying each model, see Supplementary Figure SXX.

Because the emulator transforms the discrete simulation samples into a continuous response surface at any geographic scale, it can be used for a variety of applications, including construction of continuous damage functions in a flexible format. As an example, we present global damage functions constructed from the 4D emulation, for all four dimensions tested in this study 5 (Figure 10) with the ensemble median and ensemble spread shown in bold line and ribbon. Using the emulators in this way is

helpful in the crop model intercomparison project context for diagnosing model differences. In general, across model spread is qualitatively similar across different crops and different dimensions with some notable exceptions. Model spread is highest for spring wheat in general across all dimensions. Maize has a muted response to CO₂ as a C4 plant, and the impacts of temperature are most consistent for soybeans (see also Figure 7). Increased precipitation does little to increase global production for all 5 crops except spring wheat, and rice is not generally grown in water-limited conditions so it shows the weakest response to reductions in precipitation. The nitrogen response is relatively consistent across crops, with most models showing saturation at values less than 200 kg ha⁻¹, except for soybeans, an efficient atmospheric nitrogen-fixer.

Note that these functions are presented here in Figure 10 only as examples and do not represent true global projections, because they are developed from simulation data with a uniform temperature shift while increases in global mean temperature 10 should manifest non-uniformly in space and distributions (e.g Sippel et al., 2015). The global coverage of the GGCMI Phase II simulations allows impacts modelers to apply arbitrary geographically-varying climate projections, as well as arbitrary aggregation masks, to develop damage functions for any climate scenario and any geopolitical or geographic level bigger than 0.5 degrees in latitude and longitude.

The emulator can also be used for investigating the contributions of the different major climate drivers to production outcomes 15 comes as it can project many different climate scenarios or models quickly. The emulated crop model yield responses to climate scenarios for RCP 8.5 for 5 climate models from the CMIP-5 archive (Taylor et al., 2012) are shown in Figure 11 at the yearly scale.

The differences between the emulation and the simulations for a uniform T shift are small compared to the differences 20 across different crop models. PROMET, the most quantitatively difficult models to emulate for maize, is shown in Figure 11 to illustrate that emulation error at the global production scale is still small compared to the spread across crop models or the spread across climate projections when all factors are included. The uniform temperature shift over growing area is not very different from realistic scenarios (though it biases LPJmL low). That is, projected temperature change distribution in space do not matter that much over currently cultivated area, but are likely important to production in high latitude regions which will warm much faster than lower latitudes.

Precipitation changes introduce some noise because different climate models have different P response for a given temperature 25 change. PROMET shows a near uniform reduction in yields with precipitation effects included. Including the direct effects of elevated CO₂ introduces the largest intermodel uncertainty with different crop models showing very different responses. The difference in model response to CO₂ is much larger than differences resulting from different climate model sensitivity to CO₂ (T(CO₂)). Individual climate model sensitivities can be seen in the separation in the PROMET response to CO₂. Emulation 30 based on GGCMI climatological mean shifts is useful for realistic scenarios and emulator errors are small compared to climate model differences and tiny compared to crop model differences.

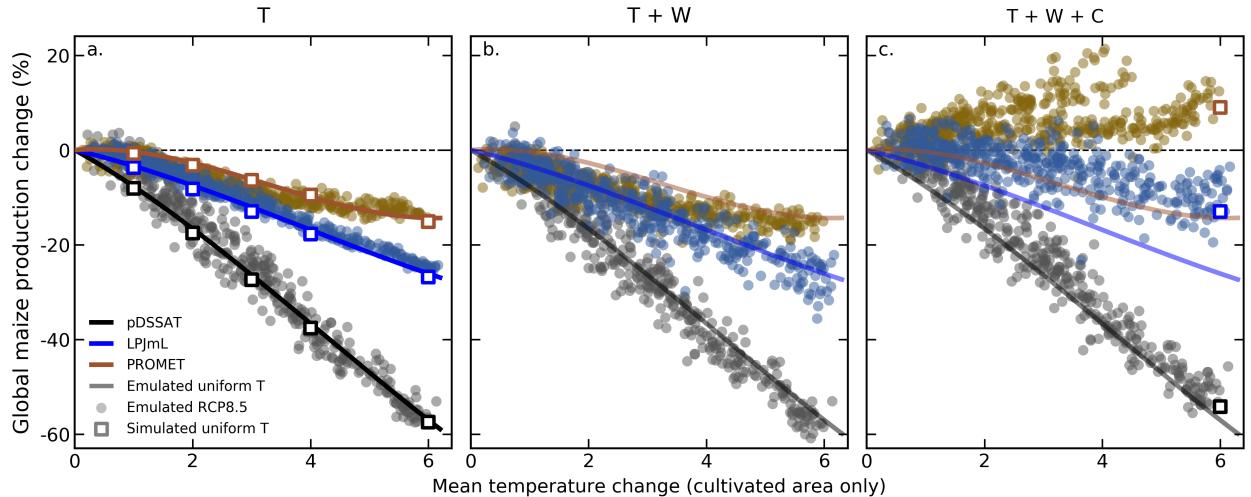

Figure 11. Illustration of the factors affecting yields in more realistic climate scenarios, for three different crop models. Figure shows emulated yield changes (relative to 1981–2010) for maize on currently cultivated land under RCP8.5 climate projections from 5 representative CMIP-5 climate models, using changes to T only (a), to T and W (b), and to T, W, and C (c). Circles are emulated yearly global production changes to 2100 ($90 \text{ years} \times 5 \text{ climate timeseries} = 450$ per crop model), with x-axis the mean historical growing-season T shift over all grid cells where maize is grown (unweighted by within-cell cultivated area). **a:** Using only temperature changes allows comparing regional simulated and emulated values. Open squares are simulated values for each T level, with CWN at baseline; bold lines are emulated values over uniform T shifts (repeated in each panel). Emulation uncertainty (compare squares to lines) is small relative to differences across climate and crop models, and mean yield changes are similar whether T changes are applied as a uniform shift or in a more realistic spatial pattern (compare lines to circles). **b:** Adding in precipitation changes increases yield spread across climate projections and depresses yield slightly for PROMET. **c:** Adding in CO₂ changes has different effects across models: CO₂ fertilization is small in pDSSAT, moderate in LPJmL, and very large in PROMET. The separation of groups of points in PROMET (gold) results because CMIP-5 climate sensitivities differ by nearly a factor of two; points at far right are under HadGEM2-ES and MIROC. In RCP8.5, the 30-year-average CO₂ at end of century is 807 ppm (ria (2007)). For comparison, open squares in c show GGCMI-II simulated production changes at T+6, W=0, C=810 ppm.

6 Discussion and conclusions

In this work we describe a new class of global gridded crop model emulators for maize, soy, rice and wheat for nine process based crop models as part of the GGCMI project. We show that the systematic parameter sampling in the GGCMI Phase II experiments allow emulating climatological crop yield responses with a relatively simple statistical model. The sampling provides information on the influence of multiple interacting factors in a way that realistic climate model simulations cannot, and allows isolating long-term impacts from confounding factors that lead to different year-over-year responses. The use of a parametric statistical model in turn offers the possibility of physical interpretation of parameter values that can assist in model intercomparison and evaluation. We show that the polynomial emulation of the mean-climatological response is feasible, with out of sample prediction errors less than 5% of yield changes both regionally and at the global scale. Critically, we show that

emulation based on uniform climate shifts is able to sufficiently reproduce the response of a crop model driven by a more realistic climate scenario at the global scale, with some relatively minor errors for rice at high latitudes.

The emulator can be used to develop standalone damage functions at any geographic scale bigger than 0.5 degree, as a proxy

for crop model sensitivity testing, or integrated directly into a larger IAM framework. The yield output for a single GGCMI

- 5 Phase II model that simulates all scenarios and all five crops is ~12.5 GB; the emulator is ~20 MB, a reduction of nearly three orders of magnitude. One-thousand years of global 0.5 degree yields (appropriately 40,000 grid cell locations) can be emulated in 20 seconds on a laptop computer.

Several cautions should be noted when using the emulator. While the emulator allows estimating agricultural impacts under arbitrary climate scenarios, extrapolation outside the sample space should be avoided. Emulators by design reduce the complexity of process-based simulations and can thus deviate from the raw simulation output. Deviations from the simulation are especially prominent in models with limited sampling or in geographic regions outside the current cultivated area. Additionally,

10 because the simulation protocol was designed to focus on change in yield under climate perturbations and not on replicating real-world yields, the models are not formally calibrated so they should not be used for impacts projections of absolute yields except in conjunction with historical yield information. Finally, because the GGCMI Phase II simulations apply uniform perturbations to historical climate inputs, they do not sample potential changes in climate variability, which may be important at high latitude locations. Although such changes are uncertain and remain poorly characterized in climate models and crop

- 15 models (e.g. Alexander et al., 2006; Kodra and Ganguly, 2014), follow-up experiments may wish to consider them. Several recent studies have described procedures for generating simulations that combine historical data with model projections of changes in the marginal distributions or temporal dependence of temperature and precipitation (e.g. Leeds et al., 2015; Poppick
20 et al., 2016; Chang et al., 2016; Haugen et al., 2018).

The GGCMI Phase II dataset and emulators invite a broad range of potential future avenues of analysis, especially because emulation allows statistical distillation of the large dataset (40 billion simulated yields) into a tractable form. Potential studies might include a detailed examination of interaction terms between the major input drivers, robust quantification of model sensitivities to input drivers, exploration of yield responses to extremes or variability, and evaluation of geographic shifts

- 25 in optimal growing regions. The dataset also enables studies of emulation itself, including a more systematic evaluation of different statistical and machine learning model specifications. In general, the development of multi-model ensembles involving systematic parameters sweeps has large promise for better understanding potential future crop responses and for improving process-based crop models.

Code and data availability. The polynomial emulator parameter matrices for all crop model emulators are available at doi.org/XXXXXX

Author contributions. J.E., C.M., A.R., J.F., and E.M. designed the research. C.M., J.J., P.F., C.F., L.F., R.C.I., I.J., C.J., W.L., S.O., M.P., T.P., A.Re., K.W., and F.Z. performed the simulations. J.F., J.J., A.S., M.L., Z.W., and E.M. performed the analysis and J.F., C.M., and E.M. prepared the manuscript.

Competing interests. The authors declare no competing interests.

5 *Acknowledgements.* We thank Michael Stein and Kevin Schwarzwald, who provided helpful suggestions that contributed to this work. This research was performed as part of the Center for Robust Decision-making on Climate and Energy Policy (RDCEP) at the University of Chicago, and was supported through a variety of sources. RDCEP is funded by NSF grant #SES-1463644 through the Decision Making Under Uncertainty program. J.F. was supported by the NSF NRT program, grant #DGE-1735359 and by an NSF Graduate Research Fellowship, grant #DGE-1746045. C.M. was supported by the MACMIT project (01LN1317A) funded through the German Federal Ministry of Education and Research (BMBF). C.F. was supported by the European Research Council Synergy grant #ERC-2013-SynG-610028 Imbalance-P. P.F. and K.W. were supported by the Newton Fund through the Met Office Climate Science for Service Partnership Brazil (CSSP Brazil). K.W. was supported by the IMPREX research project supported by the European Commission under the Horizon 2020 Framework programme, grant #641811. A.S. was supported by the Office of Science of the U.S. Department of Energy as part of the Multi-sector Dynamics Research Program Area. S.O. acknowledges support from the Swedish strong research areas BECC and MERGE together with support from 10 LUCCI (Lund University Centre for studies of Carbon Cycle and Climate Interactions). R.C.I. acknowledges support from the Texas Agrilife Research and Extension, Texas A & M University. This is paper number 35 of the Birmingham Institute of Forest Research. Computing resources were provided by the University of Chicago Research Computing Center (RCC). *This material is based upon work supported by the National Science Foundation Graduate Research Fellowship Program under Grant No. (DGE-1746045).
